AUTHENTICATION, AUTHORISATION & ACCOUNTABILITY (AAA)

KNOWLEDGE AREA

(DRAFT FOR COMMENT)

AUTHOR:  Dieter Gollmann – Hamburg University of Technology & Nanyang Technological University Singapore

EDITOR:  Emil Lupu – Imperial College London

Following wide community consultation with both academia and industry, 19 Knowledge Areas (KAs) have been identified to form the scope of the CyBOK (see diagram below). The Scope document provides an overview of these top-level KAs and the sub-topics that should be covered under each and can be found on the project website: https://www.cybok.org/.

We are seeking comments within the scope of the individual KA; readers should note that important related subjects such as risk or human factors have their own knowledge areas.

It should be noted that a fully collated CyBOK document which includes issue 1.0 of all 19 Knowledge Areas is anticipated to be released in October 2019. This will likely include updated page layout and formatting of the individual Knowledge Areas.
AUTHENTICATION, AUTHORISATION & ACCOUNTABILITY (AAA)

Dieter Gollmann

September 2019

ABSTRACT

Access control builds on authorisation and authentication. This Knowledge Area will present the generic foundations of access control and some significant instantiations that have emerged in response to changing applications. It will survey state-of-the-art authentication mechanisms and point to errors in protocol implementations where agreement properties shown for a protocol specification can be violated in its implementation. On accountability, the focus is on the management and protection of audit logs. The evaluation of the evidence collected is covered in the Forensics Knowledge Area. Throughout this chapter, we will flag technical terms that appear in more than one meaning in the academic and trade literature.

INTRODUCTION

All science is either physics or stamp collecting. [Ernest Rutherford]

In some cases, IT systems may guarantee – by design – that no undesirable behaviour is possible. In other cases, IT systems exhibit such a degree of flexibility – also by design – that additional measures need to be taken to limit undesirable behaviour specific to the given circumstances. As noted by Lessig, this can be done by code in the system that excludes behaviour which will violate certain rules, or it can be done by codes of conduct that the users of the system are expected to adhere to [1]. In the latter case, disciplinary or legal processes deal with those who break the rules. This is the context for authentication, authorisation and accountability.

Readers acquainted with the norms of academic writing may now expect definitions of core terms, some refinement of terminology, then an overview of the latest approaches in achieving authentication, authorisation and accountability. As will be shown, this approach fails at the first hurdle. All three terms are overloaded to an extent that provides ample space for confusion and dispute. For example, authorisation stands both for the setting of rules and for checking compliance with those rules. Readers should thus be cautious when studying the literature on this Knowledge Area.

Changes in the way IT is being used create their own notational challenge. How closely should terms be tied to the environment in which they first emerged? There is a habit in the trade and research literature of linking a term exclusively to a notional ‘traditional’ instantiation of a generic concept, and inventing new fashionable terms for new environments, even though the underlying concept has not changed.

CONTENT

This Knowledge Area first addresses authorisation in the context of access control and presents the main flavours of access control in use today. The section on access control in distributed systems explains concepts used when implementing access control across different sites. We will then move to authentication, touching on user authentication and on authentication in distributed systems, and conclude with a discussion of logging services that support accountability.
1 Authorisation

In their seminal paper, Lampson et al. postulate access control = authentication + authorisation [3]. We will follow this lead and present authorisation in the context of access control, starting with an introduction to the concepts fundamental for this domain, followed by an overview of different policy types. Libicki’s dictum, connotation, not denotation, is the problem [7] also applies, so we will pay particular attention to the attributes used when setting access rules, and to the nature of the entities governed by those rules. Code-based access control, mobile security, and Digital Rights Management will introduce new paradigms to access control, without changing its substance. We will then present design options for policy enforcement and discuss delegation and some important theoretical foundations of access control.

1.1 Access Control

Access control is the process of granting or denying specific requests . . . [8]. This process needs the following inputs

- Who issued the request?
- What is requested?
- Which rules are applicable when deciding on the request?

“Who” in the first question is dangerous. The word suggests that requests always come from a person. This is inaccurate for two reasons. First, the source of a request could be a particular machine, a machine in a particular configuration, or a particular program, e.g. a particular Android app. Secondly, at a technical level, requests in a machine are issued by a process, not by a person. The question thus becomes, “for whom or what is the process speaking when making the request”? “What is requested” is frequently given as a combination of an action to be performed and the object on which the action is to be performed. The rules are logical expressions that can evaluate to permit, deny, or indeterminate.

1.1.1 Core Concepts

The term ‘security policy’ is used both for the general rules within an organisation that stipulate how sensitive resources should be protected, and for the rules enforced by IT systems on the resources they manage. Sterne coined the terms organisational policies and automated policies to distinguish these two levels of discourse [2].

When setting security policies, principal stands for the active entity in an access request. When policies directly refer to users, as was the case in the early stages of IT security, user identities serve as principals. Access control based on user identities is known as identity-based access control (IBAC). In security policies that refer to concepts such as roles or to the program that issues a request, the principal is a role or a program. Principal may then generally stand for any security attribute associated with a request. With this generalization, any flavour of access control is by definition attribute-based access control (see Section 1.1.4).

Subject stands for the active entity making a request when a system executes some program. A subject speaks for a principal when the runtime environment associates the subject with the principal in an unforgeable manner. The original example for creating a subject that speaks for a principal is user log-in, spawning a process running under the user identity of the person that had been authenticated. The research literature does not always maintain this distinction between principals and subjects and
one may find security policies referring to subjects. When policies refer to attributes of a user but not to the user's identity, user identities become a layer of indirection between principals and subjects [9].

A subject is created, e.g., at log-in, and can be terminated, e.g. at log-out. Similarly, user identities are created through some administrative action and can be terminated, e.g., by deleting a user account. In practice, subjects have considerably shorter lifetimes than user identities. Subjects that could live forever, but could be killed by system crashes, are rarely deployed; processes that control industrial plants may serve as examples.

*Object* is the passive entity in an access request. *Access operations* define how an object may be accessed by a subject. Access operations can be as elementary as *read, write, execute* in Linux, they can be programs such as *setuid programs* in Linux, and they can be entire workflows as in some flavours of UCON (Section 1.1.8).

*Access rights* express how a principal may access an object. In situations where there is a direct match between access operations and access rights, the conceptual distinction between access operations and access rights may not be maintained. *Permission* is frequently used as a synonym for access right. *Privilege* may also be used as a synonym for access right, e.g., Oracle9i Database Concepts Release 2 (9.2) states:

> A privilege is permission to access a named object in a prescribed manner . . .

Other systems, such as Windows, make a distinction between access rights and privileges, using privilege specifically for the right to access system resources and to perform system-related tasks. Operating systems and databases often have a range of *system privileges* that are required for system administration.

### 1.1.2 Security Policies

*Security policies* are a collection of rules. The rules specify the access rights a principal has on an object. Conceptually, a policy could then be expressed as an *Access Control Matrix* with rows indexed by principals and columns indexed by objects [10]. *Access Control Lists* (ACLs) stored with the objects correspond to the columns of this matrix; *capabilities* stored with principals correspond to the rows of this matrix (also see *Operating Systems and Virtualisation KA*).

*Discretionary Access Control* (DAC) and *Mandatory Access Control* (MAC) are two core policies formulated in the 1970s in the context of the US defence sector. Discretionary access control policies assign the right to access protected resources to individual user identities, at the discretion of the resource owner. In the literature, DAC may generically refer to policies set by resource owners but also to policies referring directly to user identities, i.e., to IBAC.

Mandatory access control policies label subjects and objects with *security levels*. These security levels form a lattice; hence, for any two levels a least upper bound and greatest lower bound can be computed. In the literature, MAC may generically refer to policies mandated by the system as, e.g., in Security-Enhanced Linux (SELinux) [11, 12] and in Security-Enhanced (SE) Android [13], or to policies based on security levels as once in products such as Trusted Xenix or Trusted Oracle.

### 1.1.3 Role-based Access Control

In *Role-based Access Control* (RBAC), *roles* are an intermediate layer between users and the permissions to execute certain operations. Operations can be well-formed transactions with built-in integrity checks that mediate the access to objects. Users are assigned roles and are authorised to execute the operations linked to their active role. *Separation-of-duties* (SoD) refers to policies that stop single users from becoming too powerful. Examples for SoD are policies stating that more than one user needs to be involved to complete some transaction, or rules stating that policy administrators may
not assign permissions to themselves. Static SoD rules are considered during user-role assignment, dynamic SoD must be enforced when a role is activated. The NIST model for RBAC [5] distinguishes between:

- **Flat RBAC**: users are assigned to roles and roles to permissions to operations; users get permissions to execute procedures via role membership; user-role reviews are supported.
- **Hierarchical RBAC**: adds support for role hierarchies.
- **Constrained RBAC**: adds separation of duties.
- **Symmetric RBAC**: adds support for permission-role reviews, which may be difficult to achieve in large distributed systems.

Many commercial systems support some flavour of role-based access control, without necessarily adhering to the formal specifications of RBAC published in the research literature. RBAC is an elegant and intuitive concept, but may become quite messy in deployment as suggested by comments in an empirical study on the use of RBAC [14]. Practitioners note that RBAC works as long as every user has only one role, or that the enormous effort required for designing the role structure and populating role data constitutes an inhibitor for RBAC.

### 1.1.4 Attribute-based Access Control

Attribute-based Access Control (ABAC) is defined in [15] as a logical access control methodology where authorisation to perform a set of operations is determined by evaluating attributes associated with the subject, object, requested operations and, in some cases, environment conditions against policy, rules, or relationships that describe the allowable operations for a given set of attributes. This is a generic definition of access control that no longer reserves a special place to the user, or to the user’s role, reflecting how the use of IT systems has changed over time.

Access control can be performed in an application or in the infrastructure used by the application. Access control in the infrastructure uses generic attributes and operations. The Linux access control system may serve as an example. Access control in an application uses application-specific attributes and operations. In this distinction, ABAC can be viewed as a synonym for application-level access control.

### 1.1.5 Code-based Access Control

Code-based Access Control (CBAC) assigns access rights to executables. Policies may refer to code origin, to code identity (e.g., the hash of an executable), or to other properties of the executable, rather than to the identity of the user who had launched the executable. Origin can subsume the domain the code was obtained from, the identity of the code signer, a specific name space (.NET had experimented with *strong names*, i.e. bare public keys serving as names for name spaces), and more. CBAC can be found in the Java security model [16] and in Microsoft's .NET architecture [17].

The reference monitor (cf. Section 1.2.2) in CBAC typically performs a stack walk to check that all callers have been granted the required access rights. The stack walk addresses the confused deputy problem [18], where an unprivileged attacker manipulates a system via calls to privileged code (the confused deputy). Controlled invocation is implemented through *assert* statements; a stack walk for an access right will stop at a caller that asserts this right.

### 1.1.6 Mobile Security

Smartphones typically have a single owner, hold private user data, offer communication functions ranging from cell phone to NFC, can observe their surroundings via camera and microphone, and
can determine their location, e.g., via GPS. On smartphones, apps are the principals for access control. The objects of access control are the sensitive data stored on a phone and the sensitive device functions on a phone.

Access control on a smartphone has to consider the privacy requirements of the owner and the integrity requirements of the platform. Android, for example, divides permission groups into normal, dangerous, and signature permissions. Normal permissions do not raise privacy or platform integrity concerns; apps do not need approval when asserting such permissions. Dangerous permissions can impact privacy and need user approval. Up to Android 6.0, users had to decide whether to authorise a requested permission when installing an app. User studies showed that permissions were authorised too freely due to a general lack of understanding and risk awareness, see e.g. [19]. Since Android 6.0, users are asked to authorise a permission when it is first needed. Signature permissions have an impact on platform integrity and can only be used by apps authorised by the platform provider; app and permission have to be signed by the same key. For further details see the Web and Mobile KA.

1.1.7 Digital Rights Management

Digital Rights Management (DRM) has its origin in the entertainment sector. Uncontrolled copying of digital content such as games, movies or music would have a serious impact on the business models of content producers and distributors. These parties hence have an interest in controlling how their content can be accessed and used on their customers’ devices. Policies can regulate the number of times content can be accessed, how long content can be sampled for free, the number of devices it can be accessed from, or the pricing of content access.

DRM turns the familiar access control paradigm on its head. The aim now is to impose the security policy of an external party on the system owner rather than protecting the system owner from external parties. Superdistribution captures the scenario where data are distributed in protected containers and can be freely redistributed. Labels specifying the terms of use are attached to containers. The data can only be used on machines equipped with a so-called Superdistribution Label Reader that can unpack the container and track (and report) the usage of data, and enforce the terms of use [20]. The search for such a tamper resistant enforcement mechanism was one of the driving forces of Trusted Computing.

The level of tamper resistance required depends on the anticipated threats. Trusted Platform Modules are a hardware solution giving a high degree of assurance. Enclaves in Intel SGX are a solution in system software. Document readers that do not permit copying, implement this concept within an application. Sticky policies pursue a related idea [21]. Policies stick to an object and are evaluated whenever the object is accessed.

Attestation provides trustworthy information about the platform configuration. Direct anonymous attestation implements this service in a way that protects user privacy [22]. Remote attestation can be used with security policies that are predicated on the software running on a remote machine. For example, a content owner could check the software configuration at a destination before releasing the content.

For a brief period, it was fashionable to use Digital Rights Management as the generic term subsuming ‘traditional’ access control as special cases.

1.1.8 Usage Control

Usage Control (UCON) was proposed as a framework encompassing authorisations based on the attributes of subject and object, obligations, and conditions [4]. In [4], obligations are additional actions a user has to perform to be granted access, e.g. clicking on a link to agree to the terms of use. In today’s use of the term, obligations may also be actions the system has to perform, e.g.
logging the access request. Conditions are aspects independent of subject and object, e.g. time of
day when a policy permits access only during office hours or the location of the machine access is
requested from. Examples for the latter are policies permitting certain requests only when issued
from the system console, or giving access only from machines in the local network. Many concepts
from UCON have been adopted in the XACML 3.0 standard [23].

Usage control may also include provisions for what happens after an object is accessed, e.g. that a
document can be read but its content cannot be copied or adjustment of attributes after an access has
been performed, e.g. decrementing the counter of free articles a visitor may access. In another in-
terpretation, ‘traditional’ access control deals with elementary access operations while usage control
addresses entire work flows. In telecom services, usage control may put limits on traffic volume.

1.2 Enforcing Access Control

To enforce a security policy, this policy first has to be set. For a given request, a decision has to
be made about whether the request complies with the policy, which may need additional information
from other sources. Finally, the decision has to be conveyed to the component that manages the
resource requested. In the terminology of XACML, this involves

- Policy Administration Points where policies are set,
- Policy Decision Points where decisions are made,
- Policy Information Points that can be queried for further inputs to the decision algorithm,
- Policy Enforcement Points that execute the decision.

1.2.1 Delegation and Revocation

Delegation and granting of access rights both refer to situations where a principal, or a subject,
gets an access right from someone else. The research literature does not have firm definitions for
those terms, and the trade literature even less so. Granting tends to be used in a generic sense;
granted access rights often refer to the current access rights of a subject that delivers a request to a
reference monitor. Delegation is sometimes, but not always, used more narrowly for granting short-
lived access rights during the execution of a process. For example, XACML distinguishes between
policy administration and dynamic delegation that permits some users to create policies of limited
duration to delegate certain capabilities to others [24].

A second possible distinction lets delegation refer only to the granting of access rights held by the
delegator, while granting access also includes situations where a managing principal assigns access
rights to others but is not permitted to exercise those rights itself.

Rights may not always be granted in perpetuity. The grantor may set an expiry data on the delegation,
a right may be valid only for the current session, or there may be a revocation mechanism such as
the Online Certificate Status Protocol (OCSP) for X.509 certificates (see Section 2.1). OCSP is
supported by all major browsers. Revocation lists are suitable when online checks are not feasible
and when it is known in advance where a granted right may be consumed.

1.2.2 Reference Monitor

In its original definition, the reference monitor was the abstract machine mediating all accesses by
subjects to objects. The security kernel was a trustworthy implementation of the reference monitor.
The Trusted Computing Base (TCB) was the totality of protection mechanisms within a computer
system responsible for enforcing a security policy (definitions follow [25]). There has been some
interpretation creep since. The reference monitor component in current operating systems, e.g. the
Figure 1: Access Control = Authentication + Authorisation.

Security Reference Monitor in Windows, would actually be the security kernel from above, and TCB is today sometimes used in a limited sense to stand only for the security kernel. A reference monitor performs two tasks.

- It authenticate any evidence supplied by the subject with an access request. Traditionally, the user identity the subject was speaking for was authenticated.
- It evaluates the request with respect to the given policy. The early literature on access control refers to this task as authorisation (of the request), see e.g. [3].

However, authorisation also stands for the process of setting a security policy; principals are authorised to access certain resources. This overloads the term authorisation, applying it both to principals and to requests, but with different meanings. A convention that refers to “authorised principals” and “approved requests” would resolve this issue. Figure 1 represents the view of access control adopted in operating systems research around 1990. In Section 3.2.4, authorisation will stand for the granting of access rights to principals.

The decision algorithm executed by the reference monitor has to identify the applicable policies and rules, and try to collect the evidence those rules refer to from Policy Information Points. For situations where more than one rule is applicable for a given request, rule combining algorithms specify the final decision.

1.2.3 Types of Reference Monitors

Schneider describes three types of reference monitors [6]:

- Reference monitors that only see the system call to protected resources, but not the program executed. This type of reference monitor, called execution monitor in [6], is implemented in many operating systems.
- Reference monitors that can see the program and analyse its future behaviour before making an access control decision.
- Instructions guarding all security relevant operations are in-lined into the program; in all other respects the in-lined program should behave as before. This type of reference monitor, called in-line reference monitor in [6], is mostly used to deal with software security issues, see e.g. [26].

1.2.4 Protection Rings

Access control systems have to be protected from manipulation by their users. This can be achieved by letting the access control system run in an inner protection ring and the user processes in an outer ring. In the basic setting, two rings suffice. Sensitive resources such as memory can only be accessed from the inner ring.
This requires methods for controlled invocation whereby processes in the outer ring can call a process in the inner ring that executes actions on sensitive resources on the caller's behalf. Setuid programs in Unix/Linux are an example for such a method. Setuid programs are an exception to the general convention in IBAC that when a process (subject) spawns a new process, the child process inherits the parent's UID. For further details see Operating Systems and Virtualisation Security KA.

1.3 Theory

1.3.1 Security Models

Security models are high-level specifications of systems intended to enforce certain security policies. Such models can be used in a formal security analysis to show that a lower-level specification faithfully implements the model.

The Bell-LaPadula model (BLP) [27] is a state machine model for discretionary and mandatory access control policies that adapted existing rules governing access to classified data to IT systems. The mandatory access control policies state that a subject can only read objects at its own or at a lower level (no read up). To prevent unauthorised declassification of data, a subject may only write to objects at its own or at higher levels (−property, no write down). The SeaView model extends the BLP policies to multi-level secure relational databases [28]. Polyrinstantiation of database entries is used to prevent integrity checks from resulting in information leaks. BLP was highly influential in computer security into the 1990s.

The Biba model captures integrity policies based on integrity levels [29]. The access rules are the dual of the BLP model, no read down and no write up, but have no predecessors in the world of paper documents. The low watermark policies in Biba introduce dynamic policies (mutable in the terminology of UCON, Section 1.1.8) that adapt the integrity level of an object depending on the integrity level of the subject performing the access operation.

The Clark-Wilson model [30] places well-formed transactions as an intermediate layer between principals and objects; constrained data items can only be accessed via those transactions; users (principals) are ‘labelled’ with the transactions they are authorised to execute. This model captures the way data are processed in commercial settings. The Chinese Wall model [31] formalises dynamic conflict of interest policies that apply in financial consultancy businesses when working for clients that are commercial competitors. Hence, the act of accessing data for one client dynamically removes permissions to access data from other clients in the relevant conflict-of-interest class.

The Harrison, Ruzo, and Ullman model (HRU) [32] provides a context for examining a core question in policy management: is it possible to decide whether an access right may leak to a subject through some sequence of commands? This problem is undecidable in general, but may be decidable under certain restrictions.

1.3.2 Enforceable Policies

Schneider has examined the relationship between different kinds of security policies and different kinds of reference monitors [6]. Security policies are defined as predicates over execution traces. Policies that only consider the given execution trace are called properties. Information flow policies that require an execution trace to be indistinguishable from some benign execution trace are thus not properties. It is shown that only safety properties can be enforced by execution monitors (see Section 1.2.3).

1.3.3 Access Control Logics

Access control and delegation logics [33] specify calculi for reasoning about composite principals in distributed systems. The calculus for access control in distributed systems [34] was developed as
a formal specification for parts of the Digital Distributed Systems Security Architecture. In such an architecture, cryptographically secured sessions can be established between parties. E.g., when a session is established with a principal on some other machine, the session key can be treated as a subject for access control that *speaks for* that principal.

## 2 Access Control in Distributed Systems

[35], [36], [37], [38]

### INTRODUCTION

Access control in distributed systems deals with issues at the levels of technology and organisation. Any distributed system, even when maintained by a single organisation, needs mechanisms for securely transmitting access requests, attributes, policies, and decisions between nodes. These mechanisms are largely based on cryptography. The requirement for mechanisms that identify and retrieve all policies relevant for a given request may become more pronounced than in centralised settings.

In federated systems where several organisations collaborate, security policies can be set by different parties. This demands some common understanding of the names of principals, attributes, and attribute values so that policies issued by one party can be used in decisions by some other party. Arriving at such a common understanding adds to the practical challenges for RBAC listed in Section 1.1.3.

### CONTENT

We first introduce core concepts for this domain. We will then cover origin-based access control, examining cross-site scripting from the viewpoint of access control. Federated Access Control and the use of cryptography in access control are explored further.

### 2.1 Core Concepts

The literature on access control in distributed systems uses the following related terms, but the distinction between those terms is fluid.

- A *certificate* is a digitally signed data structure, created by an issuer, binding a subject (not to be confused with the term subject as introduced earlier) to some further attributes. The emphasis is on protection by a digital signature.

- A *credential* is something presented to gain access. Examples for credentials are passwords or fingerprints. In distributed systems, a credential can be a data structure containing attributes of the subject. The emphasis is on evidence submitted to the decision algorithm.

- A *token* records (‘encapsulates’) the result of some authorisation decision. For example, in operating systems the access token contains the security credentials for a login session. The emphasis is on conveying the result of an access decision to some enforcement point. So-called *bearer tokens* are not tied to a specific subject and can be used by anyone in possession of the token.

X.509 certificates [39] can be used for implementing user-centric access control. Identity certificates bind user identities to public verification keys. Attribute certificates bind user identities to access rights. Attribute certificates correspond closely to ACL entries.
2.2 Origin-based Policies

In web applications, clients and servers communicate via the HTTP protocol. The client browser sends HTTP requests; the server returns result pages. The browser represents the page internally in the document object in the Document Object Model (DOM). Security policies specify which resources a script in a web page is allowed to access, or which servers an XMLHttpRequest may refer to. Web applications are thus the principals in access control. By convention, principal names are the domain names of the server hosting an application; the policy decision point (cf. Section 1.2) at the client side is located in the browser.

The prototype policy for web applications is the same origin policy (SOP), stating that a script may only connect back to the origin it came from or that an http cookie is only included in requests to the domain that had placed the cookie. Two pages have the same origin if they share protocol, host name and port number. Certain actions may be exempt from the same origin policy. For example, a web page may contain links to images from other domains, reflecting a view that images are innocuous data without malign side effects. There exist variations of the SOP, e.g., policies for cookies that also consider the directory path.

Sender Policy Framework (SPF) [40] implements origin-based access control in the email system as a measure against spoofing the sending domain of an email. Domain owners publish SPF policies in their DNS zone. An SMTP server can then use the domain part of the MAIL FROM identity to look up the policy and consult this policy to check whether the IP address of the SMTP client is authorised to send mail from that domain.

2.2.1 Cross-site Scripting

Cross-site scripting attacks on web applications (see: Web and Mobile KA) can be treated as cases of failed authentication in access control. The browser lets all scripts that arrive in a web page speak for the origin of that page. A browser would then run a script injected by the attacker in the context of an origin other than the attacker's. Content Security Policy (CSP) refines SOP-based access control. The web server conveys a policy to the browser that characterises the scripts authorised to speak for that server [37]. Typically, this is done by specifying a directory path on the web server where authorised scripts (and other web elements) will be placed.

The use of CSP in practice has been examined in [41], observing that the unsafe-inline directive disabling CSP for all pages from a given domain was widely used. This is a familiar policy management issue. A new security mechanism is deployed but quickly disabled because it interferes too much with established practices. Moreover, CSP had an inherent vulnerability related to callbacks. Callbacks are names of scripts passed as arguments to other (authorised) scripts, but arguments are not covered by CSP. In strict CSP policies, the server declares a nonce in the CSP policy it sends to the client as the script source. The server also includes this nonce as an attribute in all scripts fetched by the client. The client's browser only accepts scripts that contain this nonce as an attribute. Nonces must only be used once and must be unpredictable.

2.2.2 Cross-origin Resource Sharing

When mashups of web applications became popular, this exposed another limitation of the same origin policy: there was no built-in mechanism for specifying exceptions to the SOP. Mashup designers initially had to find ways of circumventing the SOP enforced by the browsers. The Cross-origin Resource Sharing (CORS) protocol was then introduced to support policies for sharing resources cross-origin [42]. When a script requests a connection to a target other than its own origin, the browser asks the target to authorise the connection request. The decision at the target considers evidence supplied by the browser, such as the origin of the script or user credentials associated with the request.
CORS specifies a set of HTTP headers to facilitate this exchange. *Preflight Requests* include an Access-Control-Request-Method header that informs the server about the access intended. The server response lists methods and headers the server grants to the given origin.

The Access-Control-Allow-Credentials: true header indicates that user credentials may be provided with requests to access a resource.

### 2.3 Federated Access Control

When organisations join to form a federated security domain, the import of identities, credentials, policy rules, and decisions from different contexts (name spaces) becomes an important security issue. A federation may have several Policy Administration Points where policies are defined, Policy Decision Points where decisions on access requests are made, Policy Enforcement Points where the decisions are enforced, and Policy Information Points where additional evidence required for evaluating an access request can be obtained from.

Trust management as originally conceived in PolicyMaker [35] refers to access control systems for such scenarios. Federated identity management deals with the management of digital identities in a federation, and in particular with single sign-on in a federation. In Web Services, related standards for authentication (SAML, Section 3.2.3) and access control (XACML) have been defined. OAuth 2.0 / OpenID Connect (Section 3.2.4) provides user authentication and authorisation via access tokens.

**Binder** is an instance of a federated access control system [36]. The Binder policy language is based on Datalog. Policies are logical clauses. Binder contexts are identified by public keys and export statements by signing them with the corresponding private key. The decision algorithm is monotonic; presenting more evidence cannot reduce the access rights granted.

### 2.4 Cryptography and Access Control

Access control mechanisms in an operating system implement a logical defence. Access requests passed via the reference monitor will be policed. This includes requests for direct memory access. However, data are stored in the clear and a party with physical access to the storage medium can retrieve the data and thus bypass logical access control. When solutions for the protection of unclassified but sensitive data were evaluated in the U.S. in the 1970s, it was decided that encrypting the data was the best way forward. Access control would then be applied to the keys needed to unlock the data.

#### 2.4.1 Attribute-Based Encryption

Cloud computing has raised interest in access control on encrypted data in the past decade. Storing data in encrypted form protects confidentiality but creates a key management challenge. **Attribute-based encryption (ABE)** addresses this challenge by constructing encryption schemes that enforce attribute-based decryption policies. Policies are logical predicates over attributes, represented as access structures. The Key Generator is a Trusted Third Party that generates private keys and has to check a user’s policy / attributes before issuing a private key. The Key Generator is thus able to recreate private keys.

Key-policy attribute-based encryption (KP-ABE) works with policies that define a user’s access rights [38]. From the corresponding access structure, the Key Generator creates a private decryption key.

Documents are encrypted under a set of attributes. In ciphertext-policy attribute-based encryption (CP-ABE) [43], the policy refers to the document and the access structure is used for encryption. The user’s private key created by the Key Generator depends on the user’s attribute set. In both variants, decryption is possible if and only if the given attribute set satisfies the given access structure.

A study of the feasibility of ABE in realistic dynamic settings concluded that the overheads incurred by those schemes were still prohibitive [44]. Efficient encryption and decryption does not necessarily
imply an efficient access control system.

2.4.2 Key-centric Access Control

In distributed systems, access requests may be digitally signed. Access rights could then be granted directly to the public verification key without the need to bind the public key to some other principal. SPKI/SDSI uses authorisation certificates for implementing key centric access control, where (names of) public keys are bound to access rights [45]. The right to further delegate an access right is controlled by a delegation flag.

Cryptographic keys are rarely suitable principals for access control, however. They would need to have an obvious meaning in the application domain that provides the context for a given security policy. In most cases, cryptographic keys would be subjects speaking for some principal. Constrained delegation refines the basic delegation mechanism of SPKI/SDSI so that separation of duties policies can be enforced [46].

3 Authentication

Authentication in a narrow sense verifies the identity of a user logging in – locally or remotely – and binds the corresponding user identity to a subject. User authentication based on passwords is a common method. Some applications have adopted biometric authentication as an alternative. Authentication in distributed systems often entails key establishment. Some security taxonomies thus reduce authentication to a ‘heartbeat’ property to separate authentication from key establishment. The design of authentication protocols is a mature area in security research with good tool support for formal analysis. Standard protocols such as Kerberos, SAML, or OAuth are deployed widely today.

We will give a brief overview of password-based and biometric user authentication. We then cover authentication protocols from the Needham-Schroeder protocol via Kerberos and SAML to OAuth 2.0, observing that OAuth 2.0 is more of an authorisation protocol than an authentication protocol. We conclude with an overview of formalisations of authentication properties that serve as the basis for a formal analysis of authentication protocols.

3.1 User Authentication

Access requests are issued by subjects. Subjects can be associated with security attributes when they are created, or via delegation during their lifetime. Authentication can then be viewed as the service that validates the security attributes of a subject when it is created. When subjects are created due to some user action, and when their security attributes depend on the corresponding user identity, user authentication has to give a reasonable degree of assurance that the user identity linked to the subject belongs to the user who had triggered the creation of the subject. User authentication can also support accountability, as further elaborated in Section 4.

There are access control systems where the security attributes of a subject persist throughout the lifetime of that subject. Many operating systems adopt this approach. Policy changes do not affect active processes, but the lifetime of subjects is limited, which limits the period when the new policy is not applied consistently. Alternatively, the attributes of a subject are checked each time it issues a request. For example, a user already logged in to a banking application is authenticated again when requesting a funds transfer. When the focus moves from the subject to individual requests,
authentication can be viewed as the service that checks the validity of the security attributes submitted with the request to the decision algorithm.

### 3.1.1 Passwords

When passwords are employed for user authentication, protective measures at the system side include the storing of hashed (Unix, Linux) or encrypted (Windows) passwords, the salting of passwords, and shadow password files that move sensitive data out of world-readable password files. Protective measures at the user side include guidance on the proper choice and handling of passwords, and security awareness programs that try to instil behaviour that assures the link between a person and a principal. Recommendations in this area are changing. The Digital Identity Guidelines published by NIST build on assessments of the observed effectiveness of previous password rules and reflect the fact that users today have to manage passwords for multiple accounts [52]. The new recommendations advise

- against automatic password expiry; passwords should only be changed when there is a reason;
- against rules for complex passwords; password length matters more than complexity;
- against password hints or knowledge-based authentication; in an era of social networks too much information about a person can be found in public sources;
- to enable “show password while typing” and to allow paste-in password fields.

### 3.1.2 Biometrics for Authentication

Numerous well-rehearsed arguments explain why passwords work poorly in practice. Biometrics are an alternative that avoid the cognitive load attached to password-based authentication. Fingerprint and face recognition are the two main methods deployed for biometric user authentication, known as verification in that domain.

Biometric features must be sufficiently unique to distinguish between users, but fingerprints or faces cannot be considered as secrets. Fingerprints are left in many places, for example. Biometric features are thus better treated as public information when conducting a security analysis and the process of capturing the features during authentication has to offer an adequate level of liveliness detection, be it through supervision of that process or through device features. Employing biometrics for user authentication makes the following assumptions:

- There exist unique biometric features; face, fingerprints, and iris patterns may serve as examples.
- These features can be conveniently captured in operational settings.
- These features cannot be spoofed during user authentication.

User authentication, known as verification in biometrics, starts from a template captured by a device. From the template, a feature vector is extracted. For example, the template may be the image of a fingerprint, the features are the positions of so-called minutiae (ridge endings, bifurcations, whorls, etc.). Users initially register a reference feature vector. During authentication, a new template is captured, features are extracted and compared with the reference values. A user is authenticated if the number of matching features exceeds a given threshold. This process may fail for various reasons:
• Failure to capture: this may happen at registration when it is not possible to extract a sufficient number of features, or during authentication.

• False rejects: the genuine user is rejected because the number of matches between reference features and extracted features is insufficient.

• False accepts: some other user is accepted as the matching threshold is exceeded.

• Spoofing: to deceive the device capturing the template, some object carrying the user’s features is presented. Liveness detection tries to ensure that templates are captured from the very person that is being authenticated [53].

Biometric authentication based on face recognition or fingerprints is used increasingly at automated border control gates [54]. It has also become a feature on mobile devices, see e.g. [55]. A survey of the current state-of-the-art approaches to biometric authentication is given in [56].

3.1.3 Two-factor Authentication (2FA)

Authentication by password relies on “something you know”. Biometric authentication builds on “who you are”. In a further alternative, users are issued with a device (a.k.a. token) that computes a one-time password (OTP) synchronised with the authenticator, or a response to a challenge set by the authenticator. Possession of the device is then necessary for successful authentication, which is thus based on “something you have”.

A token could be a small hand-held device with an LED display for showing an OTP that the user then enters in a log-in form; RSA SecureID and YubiKey are examples for this type of token. A token could come with a numeric keypad in addition to the LED display and with a ‘sign’ button. The holder could then receive a challenge, e.g., an 8-digit number, enter it at the keypad, press ‘sign’ to ask the token to compute and display the response, and then enter the response in a log-in form. Some e-banking services use this type of token for account holder authentication. With PhotoTAN devices, the challenge is sent as a QR code to the user’s computer and scanned from the screen by the PhotoTAN device. Banking apps on smartphones can provide the same functionality as these tokens.

Multi-factor authentication combines several user authentication methods for increased security. The European Payment Services Directive 2 (PSD2), primarily written for the regulation of fintechs and apparently without considering device security and usability by the general public, prescribes two-factor authentication (2FA) for online payments (with a few exceptions). PSD2 thus is a case study on rolling out large scale 2FA solutions. The two factors could be a password and a token for computing transaction numbers (TANs) uniquely tied to the content of a transaction.

The token could be a separate device; if the device is tied to one payment service only, customers would have to carry multiple devices with them; for devices that can be used with several services, some level of prior standardisation is required.

The token could be a smartphone registered with the service; customers could then install apps for several services on the same device. This approach has been favoured by many banks. However, when passwords (or PINs) and TANs are handled by the same device, the two mechanisms are no longer independent, reducing the security gains claimed for 2FA.

3.2 Authentication in Distributed Systems

When methods for user authentication in distributed systems were first designed, an authenticated session took the place of a process speaking for the user. Authenticated sessions were constructed on the basis of cryptographic keys. In the terminology of Section 1.1, those session keys became the subjects of access control, and key establishment became a core feature of the user authentication process.
3.2.1 Needham-Schroeder Protocol

The Needham-Schroeder protocol is a key establishment protocol that employs an authentication server as an intermediary between a client and a server [47]. Client and server share secret keys with the authentication server respectively. Nonces, values that are used only once, are used as a defence against replay attacks. The client does not have to share individual long term secrets with all servers it wants to access, it needs just one shared secret with the authentication server. The authentication server issues a session key to client and server, and has to be trusted to properly authenticate the client and the server.

3.2.2 Kerberos

The Kerberos protocol [48] adapted the Needham-Schroeder protocol for user authentication at the MIT campus. Most major operating systems have since adopted (variations of) Kerberos for user authentication.

Users share a password with a Kerberos Authentication Server (KAS) they are registered with. From this password, the client and the KAS derive a symmetric encryption key. In its response to a client request, the KAS sends an encrypted session key to the client, together with a ticket containing that session key encrypted under a key shared between the KAS and the server. If the correct password is entered at the client, the session key can be decrypted. The ticket is forwarded to the server. Client and server now share the session key, and the server can return an authenticator constructed with the session key.

A Ticket Granting Server (TGS) may provide a further layer of indirection between client and server. The KAS would issue a session key for the TGS and a Ticket Granting Ticket (TGT) to the client. With the session key and the TGT, the client then requests a ticket for the resource server. The TGS checks the TGT and can apply an access control policy to decide whether to issue a ticket for use with the server. If the request is approved, the TGS issues another session key and a ticket encrypted under a secret key shared between TGS and server.

![Figure 2: Message flow in the Kerberos protocol.](image)

3.2.3 SAML

The Security Assertion Markup Language (SAML) v2.0 defines meta-protocols for authentication in web services [49]. Meta-protocols specify high-level message flows that can be bound to various underlying protocols such as Kerberos. Applications that use SAML for authentication then need not be aware of the underlying protocol used. Many cloud service providers (AWS, Azure, IBM, ...) are using SAML for user authentication via a browser.

Security tokens containing assertions are used to pass information about a principal (usually an end user) between a SAML authority (a.k.a. Identity Provider (IdP) or asserting party), and a SAML consumer (a.k.a. Service Provider (SP) or relying party). Assertions can be passed via the client to
the relying party (browser POST profile, Figure 3) or be pulled by the relying party from the asserting party via a handle (artefact) passed via the client (browser artefact profile, Figure 4). The specification of SAML messages and assertions is based on XML.

An authentication assertion has to include the name of the identity provider and the user identity, but this is insufficient. This was shown to be the case by an attack against the implementation of Service Provider-initiated single sign-on with Redirect/POST Bindings used at that time in Google Applications [57]. In this implementation, authentication assertions included the two aforementioned fields. A malicious Service Provider could ask a user for authentication at a specific Identity Provider (step 0 in Figure 3) and then re-use the assertion to impersonate the user with another Service Provider that relied on the chosen Identity Provider and where the user was known by the same user identity, e.g., an email address.

The specification of SAML Redirect/POST Bindings includes the SID and a request ID issued by the Service Provider in the authentication assertion. Hence, a Service Provider would only accept an assertion issued in reaction to a pending authentication request.

![Figure 3: Message flow in the SAML POST profile.](image)

![Figure 4: Message flow in the SAML artefact profile.](image)

SAML was introduced as a meta-protocol to isolate web services from underlying authentication protocols and from different underlying communication protocols. It was conceived as a federated single sign-on protocol where the relying party decides how to use assertions when making decisions according to its own security policy.

In the practical deployment of SAML, parsing XML documents - the price to be paid for employing a meta-protocol - can create non-trivial overheads and introduce security vulnerabilities. Furthermore, the advent of smartphones has made it easier to access the internet from mobile user devices, removing one of the reasons for introducing a meta-protocol between web services and the underlying IT systems.
3.2.4 OAuth 2 – OpenID Connect

Current protocols such as OAuth 2.0 [50] and OpenID Connect [58] run directly over HTTP and provide authentication and authorisation. The parties involved include a user who owns resources, the resource owner, a resource server that stores the user’s resources, a so-called client application that wants to be granted access to those resources, and an authorisation Server (AS) that can authenticate users and client applications.

Clients have to be registered with the AS. They will receive a public client ID and a client secret shared with the AS. This secret is used for establishing secure sessions between the client and the AS. The client also registers redirect URIs with the AS. The AS will redirect a user agent only to those registered redirect URIs. Proper definition of the redirect URIs is primarily a matter for the client, and can also be enforced by the AS. Weak settings are open to exploitation by attackers.

In an OAuth protocol run (Figure 5), the user agent (browser) has opened a window for the client application. In the client window, an authorisation request can be triggered, typically sent to the AS; the request also contains a redirect_URI. The AS then opens a window in the user agent to let the resource owner authorise client access to the resource. A secure session between the user agent and the AS is required, and may already exist if the user has logged in previously at the AS. If successful, an authorisation grant is returned to the user agent, which will pass it on to the redirect_URI given by the client. The client then posts the authorisation grant and a redirect URI to the AS. It is assumed that the AS can authenticate this message as coming from the client. If the request is valid, the AS returns an access token to the redirect URI provided, where the token can be used to retrieve the resource from the resource server.

Authorisation requests and authorisation grants are linked via a request ID, called state in OAuth. Omitting the request ID or using a fixed value will introduce vulnerabilities in applications using OAuth, see e.g. [59, 60].

There is a fundamental switch in focus compared to SSO protocols such as Kerberos and SAML despite a considerable degree of similarity in the message flows. In an OAuth 2.0 protocol run the user is no longer the party requesting access to a resource owned by someone else, but the party granting access to resources owned by the user. OAuth 2.0 and OpenID Connect are thus known as authorisation protocols.

There are several assumptions about pre-existing trust relationships between parties that are important for the security of OAuth. Conversely, one cannot take for granted that the OAuth security properties still hold when deploying the protocol in a new setting.

3.3 Facets of Authentication

We have sketched how user authentication in distributed systems first integrated session and key establishment with the process of verifying a user’s identity, and later established authorisation prac-
tices to access a user’s resources. In communication security, peer entity authentication refers to the process of verifying the identity of the peer in a connection and data origin authentication to the process of verifying the origin of individual data items.

User authentication, whether relating to a local system or to a remote system, entails three aspects:

- creating a new subject, e.g. a new process or a new session with a fresh session key,
- linking an internal entity, e.g. a user ID, to the subject,
- linking an external entity, e.g. a person, to an internal identity.

To differentiate between these aspects, the term key establishment was introduced in communication security towards the end of the 1980s for the first aspect. Entity authentication stood for what was left. Quoting ISO/IEC 9798, entity authentication mechanisms allow the verification, of an entity’s claimed identity, by another entity. The authenticity of the entity can be ascertained only for the instance of the authentication exchange. This property is related to dead peer detection and to the heartbeat extension in RFC 6250 [61]. Note that this definition does not distinguish between internal and external entities.

3.3.1 Patterns for Entity Authentication

Entity authentication according to the definition in ISO/IEC 9798 can be implemented with challenge response-mechanisms. When prover and verifier share a secret, the verifier sends an unpredictable challenge to the prover who constructs its response as a function of the challenge and the shared secret. For example, HTTP digest authentication uses the hash of the challenge, a password, and further data that binds authentication to a particular HTTP request.

When public key cryptography is used, the verifier needs the prover’s public key. With a digital signature scheme, the verifier could send the challenge in the clear and the prover could respond with the signed challenge. With a public key encryption scheme, the verifier could encrypt the challenge under the prover’s public key; a response constructed from the decrypted challenge would authenticate the prover. The latter mechanism is used with Trusted Platform Modules (TPM) where successful decryption of data encrypted under the public endorsement key of a TPM authenticates the TPM.

3.3.2 Correspondence Properties

The Public-Key Needham-Schroeder protocol uses public key encryption with its challenge-response mechanism [47]. In this protocol, a malicious prover could decrypt a challenge and reuse it in a protocol run with a third party pretending to be the original verifier; the third party would then respond to the verifier although the verifier is not engaged in a protocol run with the third party [51]. This scenario would amount to an attack if the mismatch in the assumptions about a protocol run is security relevant. The attack would be detected if the identities of prover and verifier are included in all messages. Note that in this ‘attack’ the verifier still correctly concludes that the prover is alive.

Matches in the assumptions about aspects of a protocol run held by the peers on completion of a run can be captured by correspondence properties, as proposed in [62] and further elaborated in [63]:

- **Aliveness**: whenever the verifier (initiator) concludes a protocol run, the prover had also been engaged in a protocol run.
- **Weak agreement**: whenever the verifier (initiator) concludes a protocol run apparently with a given prover, the prover had also been engaged in a protocol run, apparently with that verifier.
• **Non-injective agreement**: whenever the verifier (initiator) concludes a protocol run apparently with a given prover, the prover had also been engaged in a protocol run, apparently with that verifier, and responder and receiver agree on a specified set of data items pertaining to a protocol run.

• **Agreement**: whenever the verifier (initiator) concludes a protocol run apparently with a given prover, the prover had also been engaged in a protocol run, apparently with that verifier, and responder and receiver agree on a specified set of data items pertaining to a protocol run, and each protocol run of the verifier corresponds to a unique protocol run of the prover.

In the vulnerable Redirect/POST Binding in Google Applications there is no agreement on the service provider an authentication assertion is intended for ([57], Section 3.2.3). Flawed implementations of OAuth that use a fixed value for the state variable do not even guarantee aliveness ([59], Section 3.2.4).

Correspondence properties are intensional properties well suited for protocol analysis using model checking. This line of research had reversed the earlier decision to separate pure entity authentication from agreeing on session keys and again added agreement on certain data items to authentication.

3.3.3 Authentication as Verified Association

Returning to a holistic view on authentication, one could use this as a general term for mechanisms that create a new subject and associate it with evidence relevant for access decisions. If this route is taken, verifying the identity of a user becomes just a special case of authentication.

There would, furthermore, be merit in distinguishing between association with internal and external entities. The latter case is an instance of the ‘difficult and error prone’ problem of faithfully representing aspects of the physical world within an IT system. The veracity of such representations cannot be guaranteed by cryptographic means alone. For example, access control in distributed systems may make use of public key cryptography (Section 2.4.2). Public keys can then be interpreted as subjects in the context of access control. The checks performed by a certificate authority before it issues a certificate amount to authentication.

3.3.4 Authentication for Credit or for Responsibility

Authentication may give credit to an entity for actions it has performed, or of establishing which entity is responsible for an action [64]. In the first case, an attack amounts to earning undeserved credits and authentication is broken if the attacker succeeds in making a victim perform actions under the attacker’s identity. In the second case, an attack amounts to deflecting responsibility to someone else and authentication is broken if the attacker succeeds in performing actions under the victim’s identity.

4 Accountability

**INTRODUCTION**

Accountability has been defined as the security goal that generates the requirement for actions of an entity to be traced uniquely to that entity. This supports non-repudiation, deterrence, fault isolation, intrusion detection and prevention, and after-action recovery and legal action [8].

This definition invites investigations into psychology to determine what makes an effective deterrent, investigations into legal matters to determine the standard of evidence demanded in a court of law, and technical investigations into the collection, protection, and analysis of evidence. This Knowledge Area will focus on those technical aspects.
We will cover the technical prerequisites for accountability. We will briefly explore potential conflicts between privacy and accountability, describe current activities in distributed logging of events, and refer to some related terms that overlap with accountability.

4.1 Technical Aspects

Accountability supports processes that are launched after events have occurred. Such a process may be a regular audit that checks whether an organisation complies with existing regulations. It might represent a technical audit that scans logs in search for signs of a cyber attack. It may also be an investigation triggered by an incident that tries to identify the vulnerabilities exploited, or an investigation that tries to identify the parties responsible. In all cases, the quality of the evidence is decisive.

The aforementioned processes make use of logs of events. Such logs may be kept by the operating system, by networking devices, or by applications (Section 4.2 will give an example). The nature of the events depends on the activity that is being monitored.

4.1.1 Audit Policies

Accountability is only as strong as the quality of evidence collected during operations. System administrators may set audit policies that define which events will be logged. Operating systems and audit tools provide menus to guide administrators through this task. Access control policies that specify as obligations that certain requests must be logged also influence which evidence is collected.

4.1.2 Preserving the Evidence

Accountability is only as strong as the protection of the evidence collected during operations. Attackers could try to hide their traces by deleting incriminating log entries once they have acquired sufficient privileges. They could then modify audit policies so that future actions are not recorded, but should not be able to tamper with the evidence already collected.

Tamper resistance could rely on physical measures like printing the log on an endless paper reel or writing the log to WORM (write-once, read-many) memory like an optical disk. Tamper resistance could be supported by cryptography. Storing the log as a hash chain [65, 66] makes it evident when entries have been removed, but does not guarantee that entries cannot be lost.

Audit policies have to address situations where logging is disrupted, e.g., because the log file has run out of space. Is it then acceptable to overwrite old entries or should the system be stopped until proper auditing is again enabled? This conflict between availability and accountability has to be resolved.

4.1.3 Analysing the Evidence

Audit logs can create large volumes of data and many entries are not security relevant so that automated processing is required. Known attack patterns can be detected by their signatures. Machine learning techniques can help to detect anomalies. Lessons learned when applying this approach to network intrusion detection are discussed in [67]. Visualisation techniques try to draw the administrators’ attention to the most relevant events.

4.1.4 Assessing the Evidence

Accountability is only as strong as the method of user authentication when legal or disciplinary actions are to be supported. This relates to technical aspects of the authentication mechanism and also to
user resilience to phishing and social engineering attacks. Telling users not to fall for obvious phishing attacks is easy, but a well-designed spear phishing attack will not be obvious.

Accountability is only as strong as the organisational security policies on connecting devices, e.g. USB tokens, internal systems, and policies on access to external web sites. Accountability is only as strong as the defences against software vulnerabilities that can be exploited to run code under a user identity without the user being aware of that fact, e.g. so-called drive-by-downloads.

4.2 Privacy and Accountability

Privacy rules can have an impact on the events that may be logged. Employment law may, for example, limit how closely a company monitors its employees, which might make it difficult to achieve accountability when rules have been broken.

Sometimes, there are technical resolutions to such conflicts between legal goals. Take the example of a company that does not log which external websites an employee connects to: when an external site is attacked from within the company network, it is desirable that the perpetrator can be held accountable. To achieve both goals, the company gateway would log for outgoing requests only the internal IP address and the port number used with the global IP address. As there is no record of the visited website, it becomes harder to establish the link between the internal IP address and the visited site, whereas if the website was known, it could provide the port number the attack came from.

Conversely, logging may have unintended privacy impacts. Take Certificate Transparency [RFC 6962] as an example. Certificate Transparency is a logging service for the issuers of TLS certificates. Participating Certificate Authorities record the issuance of certificates with this service. Domain owners can scan the log for certificates for their domain that they had not asked for, i.e., detect authentication failures at issuers. This service was introduced in reaction to attacks where such misissued certificates had been used to impersonate the domain affected, and makes issuers accountable to domain owners.

Private subdomains are subdomains created for internal use only. When a certificate for a private subdomain is requested, the certificate will be recorded in the Certificate Transparency log disclosing the existence of the private subdomain to the public [68].

4.3 Distributed Logs

Logs may be kept to hold the users or the owner of a system accountable. In the case of the owner, auditors may require that the logging device is sealed, i.e., rely on a physical root of trust. Alternatively, logs could be kept in a distributed system run by independent nodes where there are sufficient barriers to forming alliances that can take over the system.

The nodes maintaining the log need to synchronise their versions of the log. The overheads for synchronisation, or consensus, depend on the failure model for the nodes and for the communication network, and on the rules for joining the distributed system. Systems may be open for anyone, or be governed by a membership service. The recent interest in blockchains extends to this type of logging solutions.

4.4 Related Concepts

The definition at the start of Section 4 refers to non-repudiation and intrusion detection. Non-repudiation has a specific meaning in communication security, viz. providing unforgeable evidence that a specific action occurred. This goal is not necessarily achieved by logging mechanisms; they may protect the entries recorded, but may record entries that have already been manipulated.

Intrusion detection is a knowledge area of its own with overlapping goals. Intrusion detection does not have the requirement for actions of an entity to be traced uniquely to that entity. The focus will be
more on detecting attacks than detecting the attacker. The evaluation of log data is addressed in the *Forensics KA*.

The definition given subsumes both the accountability of legal persons and technical investigations into security breaches. The standards on evidence may be higher in the first case. Tracing actions unique to an entity leads to **cyber attribution**, the process of tracking and identifying the perpetrators of cyber attacks. Circumstantial evidence such as similarity in malware may be used in this process, and mis-attribution due to **false flag operations** is an issue. Calling for DRM to protect the intellectual property of content owners, because digital content can be copied so easily, but assuming that malware cannot be copied would be incongruous.

**CONCLUSIONS**

Access control has kept adapting to the changing applications of IT systems. Access control was originally conceived for the protection of sensitive data in multi-user and multi-level secure systems. Access control without user identities was unthinkable. Applications have since changed and some require new modes of access control. One could then reserve ‘access control’ for the original setting and invent new terms for each new flavour of access control. DRM may serve as an example. This Chapter has not taken this route but applied ‘access control’, ‘authentication’, and ‘authorisation’ more generally while staying true to the generic meanings of these terms. User identities have lost their prominence along this way. Code (apps) and web domains have taken their place.

Authentication originally stood for the service that links external entities like human users to internal actions in the IT system; today, it may also denote the service that verifies evidence associated with access requests that are submitted for evaluation by a decision algorithm. Design and analysis of cryptographic authentication protocols for distributed systems is a mature knowledge area. Cryptographic solutions for other aspects of access control are often more of academic than of practical interest.

Accountability services build on tamper resistant records of events. The evidence collected may serve as input for technical investigations that try to establish how an attack was conducted and to identify its effects. The evidence collected may also be used in disciplinary processes that deal with situations where rules were broken at the level of the persons implicated. Privacy rules may put limits on the events that are recorded, and the nature of the events recorded may reduce privacy in ways not anticipated.
